18 **Abstract**

19
20 This paper presents the regional travel forecasting model system (SACSIM) being used by the
21 Sacramento (California) Area Council of Governments (SACOG). Within SACSIM an integrated activity-
22 based disaggregate econometric model (DaySim) simulates each resident's full-day activity and travel
23 schedule. Sensitivity to neighborhood scale is enhanced through disaggregation of the modeled outcomes in
24 three key dimensions: purpose, time, and space. Each activity episode is associated with one of seven
25 specific purposes, and with a particular parcel location at which it occurs. The beginning and ending times of
26 all activity and travel episodes are identified within a specific 30-minute time period. Within SACSIM,
27 DaySim equilibrates iteratively with traditional traffic assignment models. SACSIM was calibrated and
28 tested for a base year of 2000 and for forecasts to the years 2005 and 2035, and was subjected to a formal
29 peer-review. It was used to provide forecasts for the Regional Transportation Plan (RTP) and continues to be
30 used for various policy analyses.

31 The paper explains the model system structure and components, the integration with the traffic
32 assignment model, calibration and validation, sensitivity tests, model application and Federal peer review
33 results. We conclude that it is possible to create and apply a regional demand model system using parcel-
34 level geography and half-hour time of day periods. Experiences thus far have pointed to major benefits of
35 using detailed land use variables and urban design variables, but also to new challenges in providing parcel-
36 level land use inputs for future years.

37
38 *Keywords: travel demand forecasting, activity-based models, microsimulation*

1 Introduction

Over the last decade, activity-based travel demand microsimulation models have gradually gained acceptance in the U.S. as the eventual successor to conventional “four step” travel demand models for large metropolitan areas. Activity-based model systems have been applied in Portland (Bradley, et al., 1998; Bradley, et al., 1999), San Francisco (Bradley, et al., 2001; Jonnalagadda, et al., 2001), New York (Vovsha, et al., 2002); Columbus (Vovsha, et al., 2003); Dallas (Bhat, et al. 2004), and Sacramento. Bradley and Bowman (2006) provide a detailed comparison of the properties of those model systems, as well as references to papers written about those models.

In 2009, additional activity-based model systems have reached various stages of development for Denver, Seattle, Bay Area, San Diego, Atlanta, Los Angeles and Phoenix. We have now reached the point where the majority of new travel demand model development projects for major metropolitan areas in the US are for activity-based model systems.

The innovative features of the new activity-based models systems that tend to receive the most attention are the use of tours in addition to trips as a basic unit of behavior, attention to how activities are generated and scheduled across an entire day, and, in some cases, how different household members interact to influence each others’ travel decisions. Another important aspect that tends to receive less attention is that using disaggregate microsimulation of individual households and persons instead of the conventional aggregate zone-based framework provides the potential for much finer levels of spatial and temporal detail in the forecasts. To date, most of the applied activity-based models continued to rely on zones as the spatial level of detail, and to rely on four or five broad time periods of the day as the temporal level of detail. There has been some skepticism that the new activity-based model framework would be able to improve upon those typical levels of resolution.

The purpose of this article is to provide a detailed description of an operational activity-based model that takes advantage of the disaggregate microsimulation framework to provide much finer levels of resolution in forecasting. The Sacramento model system described below uses 48 half-hour time periods across the day as the basic units of temporal resolution, and uses individual parcels of land as the basic units of spatial resolution. This latter feature in particular is quite significant, given that a metropolitan area typically has over one million parcels, as compared to less than a few thousand traffic analysis zones. Using parcel-level resolution allows regional travel demand models to include land use variables and urban design variables at a level of detail that has not been possible in the past, allowing planners to look at wider range of land use and infrastructure policies, particularly those that affect non-motorized travel and accessibility to transit services.

2 SACSIM Model System Overview

This paper presents a regional travel forecasting model system called SACSIM, implemented by the Sacramento (California) Area Council of Governments (SACOG). The system includes an integrated econometric microsimulation of personal activities and travel with a highly disaggregate treatment of the purpose, time of day and location dimensions of the modeled outcomes. SACSIM will be used for transportation and land development planning, and air quality analysis.

Figure 1 shows the major SACSIM components. The Representative Population Generator creates a synthetic population, comprised of households drawn from the region’s U.S. Census Public Use Microdata Sample (PUMS) and allocated to parcels. Long-term choices (work location, school location and auto ownership) are simulated for all members of

88
89
90
91
92
93
94

the population. The Person Day Activity and Travel Simulator (DaySim) then creates a one-day activity and travel schedule for each person in the population, including a list of their tours and the trips on each tour. The DaySim components, implemented in a single custom software program, consist of a hierarchy of multinomial logit and nested logit models. The models within DaySim are connected by adherence to an assumed conditional hierarchy, and by the use of accessibility logsums.

95
96
97

Figure 1: SACOG Regional Travel Forecasting Model System (SACSIM)

97 The trips predicted by DaySim are aggregated and combined with predicted airport
98 passenger trips, external trips and commercial vehicle trips into time- and mode-specific trip
99 matrices. The network traffic assignment models load the trips onto the network. Traffic
100 assignment is iteratively equilibrated with DaySim and the other demand models.

101 As shown here, the regional forecasts are treated as exogenous. In subsequent
102 implementations, it is anticipated that SACSIM will be fully integrated with PECAS,
103 Sacramento's new land use model (Abraham, Garry and Hunt, 2004), so that the long range
104 PECAS forecasts will depend on the activity-based travel forecast of DaySim..
105

106 **2.1 DaySim Overview**

107
108 DaySim follows the day activity schedule approach developed by Bowman and Ben-Akiva
109 (2001). Its features include the following:

110 • The model uses a microsimulation structure, predicting outcomes for each
111 household and person in order to produce activity/trip records comparable to those from a
112 household survey (Bradley, et al, 1999).

113 • The model works at four integrated levels—longer term person and household
114 choices, single day-long activity pattern choices, tour-level choices, and trip-level choices

115 • The upper level models of longer term decisions and activity/tour generation are
116 sensitive to network accessibility and a variety of land use variables.

117 • The model allows the specific work tour destination for the day to differ from the
118 person's usual work location.

119 • The model uses seven different activity purposes for both tours and intermediate
120 stops (work, school, escort, shop, personal business, meal, social/recreation).

121 • The model predicts locations down to the individual parcel level.

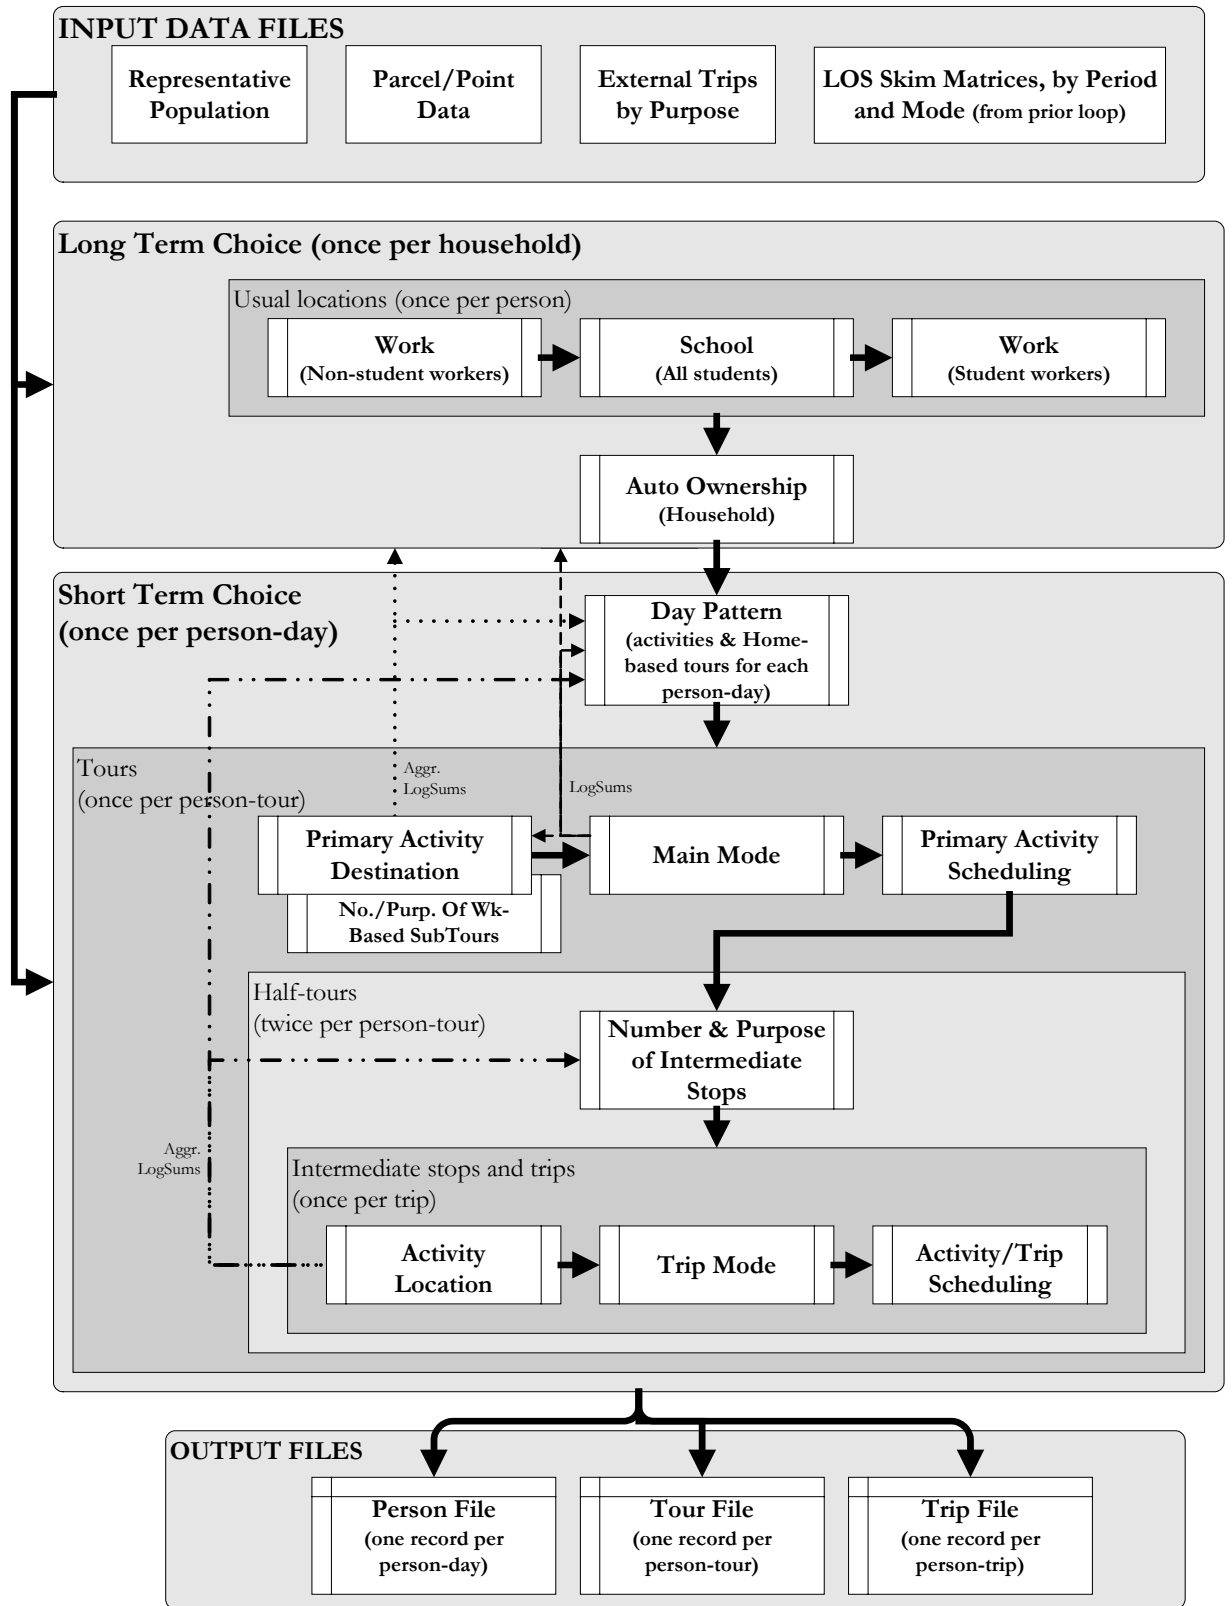

122 • The model predicts the time that each trip and activity starts and ends to the
123 nearest 30 minutes, using an internally consistent scheduling structure that is also sensitive
124 to differences in travel times across the day (Vovsha and Bradley, 2004).

125 • The model is highly integrated, including the use of mode choice logsums and
126 approximate logsums in the upper level models, encapsulating differences across different
127 modes, destinations, times of day, and types of person.

128 The latter four features are enhancements relative to its closest precursor, the CHAMP
129 model currently in active use by the San Francisco County Transportation Authority
130 (SFCTA). See Bradley, et al. (2001) and Jonnalagadda, et al. (2001) for details of the
131 SFCTA model.

132 Figure 2 is a flow diagram showing the relationships among DaySim's component
133 models, which are also listed in Table 2. The models themselves are numbered hierarchically
134 in the table; subsequently in this paper, parenthetical numerical references to models refer to
135 these numbers. The hierarchy embodies assumptions about the relationships among
136 simultaneous real world outcomes. In particular, outcomes from models higher in the
137 hierarchy are treated as known in lower level models. It places at a higher level those
138 outcomes that are thought to be higher priority to the decision maker. The model structure
139 also embodies priority assumptions that are hidden in the hierarchy, namely the relative
140 priority of outcomes on a given level of the hierarchy. The most notable of these are the
141 relative priority of tours in a pattern, and the relative priority of stops on a tour. The formal

142 hierarchical structure provides what has been referred to by Vovsha, Bradley and Bowman
143 (2004) as downward vertical integrity.
144

144

146

Figure 2: DaySim Flow Diagram

| Model # | Model Name | Level | What is predicted |
|---------|---------------------------------|------------|------------------------------------------------------------------------------------------------------------------------------------|
| 1.1 | Synthetic Sample Generator | Household | Household size and composition, household income, person age, gender, employment status, student status |
| 1.2 | Regular Workplace Location | Worker | Workplace location zone and parcel |
| 1.3 | Regular School Location | Student | School location zone and parcel |
| 1.4 | Auto Ownership | Household | Auto ownership |
| 2.1 | Daily Activity Pattern | Person-day | 0 or 1+ tours for 7 activity purposes. 0 or 1+ stops for 7 activity purposes |
| 2.2 | Exact Number of Tours | Person-day | For purposes with 1+ tours, 1, 2 or 3 tours. |
| 3.1 | Tour Primary Destination Choice | (Sub)Tour | Primary destination zone and parcel (models are purpose-specific) |
| 3.2 | Work-Based Subtour Generation | Work Tour | Number and purpose of any subtours made during a work tour |
| 3.3 | Tour Main Mode Choice | (Sub)Tour | Main tour mode (models are purpose-specific) |
| 3.4 | Tour Time of Day Choice | (Sub)Tour | The time period arriving and the time period leaving primary destination (models are purpose-specific) |
| 4.1 | Intermediate Stop Generation | Half Tour | Number and activity purpose of any intermediate stops made on the half tour, conditional on day pattern |
| 4.2 | Intermediate Stop Location | Trip | Destination zone and parcel of each intermediate stop, conditional on tour origin, destination, and location of any previous stops |
| 4.3 | Trip Mode Choice | Trip | Trip mode, conditional on main tour mode |
| 4.4 | Trip Departure Time | Trip | Departure time within 30 min. periods, conditional on time windows remaining from previous choices |

147

148

Table 2. Component Models of DaySim

149 Just as important as downward integrity is the upward vertical integrity that is achieved
 150 by the use of composite accessibility variables to explain upper level outcomes. Done
 151 properly, this makes the upper level models sensitive to important attributes that are known
 152 only at the lower levels of the model, most notably travel times and costs. It also captures
 153 non-uniform cross-elasticities caused by shared unobserved attributes among groups of
 154 lower level alternatives sharing the same upper level outcome.

155 Upward vertical integration is a very important aspect of model integration. Without it,
 156 the model system will not effectively capture sensitivity to travel conditions. However, when
 157 there are very many alternatives (millions in the case of the entire day activity schedule
 158 model), the most preferred measure of accessibility, the expected utility logsum, requires an
 159 infeasibly large amount of computation. So, for SACSIM approaches have been developed
 160 to capture the most important accessibility effects with a feasible amount of computation.
 161 One approach involves using logsums that approximate the expected utility logsum. They
 162 are calculated in the same basic way, by summing the exponentiated utilities of multiple
 163 alternatives. However, the amount of computation is reduced, either by ignoring some
 164 differences among decisionmakers, or by calculating utility for a carefully chosen subset or
 165 aggregation of the available alternatives. The approximate logsum is pre-calculated and used
 166 by several of the model components, and can be re-used for many persons. Two kinds of
 167 approximate logsums are used, an approximate tour mode/destination choice logsum and an
 168 approximate intermediate stop location choice logsum. The approximate tour mode-
 169 destination choice logsum is used in situations where information is needed about
 170 accessibility to activity opportunities in all surrounding locations by all available transport
 171 modes at all times of day. The approximate intermediate stop location choice logsum is used
 172 in the activity pattern models, where accessibility for making intermediate stops affects
 173 whether the pattern will include intermediate stops on tours, and how many.

174 The other simplifying approach involves simulating a conditional outcome. For
 175 example, in the tour destination choice model, where time-of-day is not yet known, a mode
 176 choice logsum is calculated based on an assumed time of day, where the assumed time of day
 177 is determined by a probability-weighted Monte Carlo draw. In this way, the distribution of
 178 potential times of day is captured across the population rather than for each person, and the
 179 destination choice is sensitive to time-of-day changes in travel level of service.

180 In many other cases within the model system, true expected utility logsums are used.
 181 For example, tour mode choice logsums are used in the tour time of day models.
 182

183 **3 Component Models of DaySim**

184
 185 The models in the DaySim component of SACSIM were estimated using data from the 1999
 186 Sacramento Area Household Travel Survey, fielded by NuStats. The survey was a fairly
 187 standard place-based one-day travel diary survey, very similar to most other regional
 188 household travel surveys carried out in the US during the last decade.

189 We do not have the space in this paper to provide details on the exact specification or
 190 estimation results for each component model. Table 1 provides a summary of most of the
 191 explanatory variables used in the models. The reader is referred to the SACSIM Technical
 192 Memos (Bowman and Bradley, 2005-6), available on the website <http://JBowman.net>, as well
 193 as the *SACSIM07 Model Reference Report* (SACOG 2008). The following sections list some
 194 key aspects of the various DaySim component models. Similar models are grouped together,
 195 for ease of presentation.

This model is a variation on the Bowman and Ben-Akiva approach, jointly predicting the number of home-based tours a person undertakes during a day for seven purposes, and the occurrence of additional stops during the day for the same seven purposes. The seven purposes are work, school, escort, personal business, shopping, meal and social/recreational. The pattern choice is a function of many types of household and person characteristics, as well as land use and accessibility at the residence and, if relevant, the usual work location. The main pattern model (2.1) predicts the occurrence of tours (0 or 1+) and extra stops (0 or 1+) for each purpose, and a simpler conditional model (2.2) predicts the exact number of tours for each purpose. The “base alternative” in the model is the “stay at home” alternative where all 14 dependent variables are 0 (no tours or stops are made).

Many household and person variables were found to have significant effects on the likelihood of participating in different types of activities in the day, and on whether those activities tend to be made on separate tours or as stops on complex tours. The significant variables include employment status, student status, age group, income group, car availability, work at home dummy, gender, presence of children in different age groups, presence of other adults in the household, and family/non-family status. For workers and students, the accessibility (mode choice logsum) of the usual work and school locations is positively related to the likelihood of traveling to that activity on a given day. For workers, the accessibility to retail and service locations on the way to and from work is positively related to the likelihood of making intermediate stops for various purposes.

Simpler models were estimated to predict the exact number of tours for any given purpose, conditional on making 1+ tours for that purpose. An interesting result is that, compared to the main day pattern model, the person and household variables have less influence but the accessibility variables have more influence. This result indicates that the small percentage of people who make multiple tours for any given purpose during a day tend to be those people who live in areas that best accommodate those tours. Other people will be more likely to participate in fewer activities and/or chain their activities into fewer home-based tours.

The DaySim models implemented in Sacramento do not include explicit models of intra-household interactions. Although explanatory variables are used throughout the model system to take account of the characteristics of other household members, we do not explicitly link the activity patterns across individuals so that they travel together. During the period that the Sacramento model system was being developed, the first such applied intra-household interaction models of that type were being developed and applied for the Columbus and Atlanta regions. For Sacramento, on the other hand, the focus was placed on using finer level spatial detail (parcels) and temporal detail (30 minute periods), as well as on achieving upward integrity through consistent use of accessibility logsums at all levels of the model system. Adding models of explicit intra-household interactions may be a worthwhile additional during future model update projects (along with other potential improvements described in the final section of this paper).

243 **3.2 Generation Model for Work-based Subtours**

For this model, the work tour destination is known, so variables measuring the number and accessibility of activity opportunities near the work site influence the number and purpose of work-based tours. This model is very similar in structure to the stop participation and purpose models described next.

3.3 Generation Model for Intermediate Stops on Half-Tours

For each tour, once its destination, timing and mode have been determined, the exact number of stops and their purposes is modeled for the half-tours leading to and from the tour destination. For each potential stop, the model predicts whether it occurs or not and, if so, its activity purpose. This repeats as long as another stop is predicted. The outcomes of this model are strongly conditioned by (a) the outcome of the day activity pattern model, and (b) the outcomes of this model for higher priority tours. For the last modeled tour, this model is constrained to accomplish all intermediate stop activity purposes prescribed by the activity pattern model that have not yet been accomplished on other tours.

The estimation results for this model indicate that accessibility measures are important in determining which stops are made on which tours, as well as the exact number of stops. An important feature of this model system is that we do not predict the number and allocation of stops completely at the upper pattern level, as is done in the Portland and SFCTA models, or completely at the tour level, as is done in other models such as those in Columbus and New York. Rather, the upper level pattern model predicts the likelihood that ANY stops will be made during the day for a given purpose, at a level where the substitution between extra stops versus extra tours can be modeled directly. Then, once the exact destinations, modes and times of day of tours are known, the exact allocation and number of stops is predicted using this additional tour-level information. We think that this approach provides a good balance between person-day-level and tour-level sensitivities.

3.4 Location Choice Models

3.4.1 Usual Work and School Locations and Tour Primary Destinations

The dependent variable in the usual location and tour destination models is the parcel address where the activity takes place. Since over 700,000 parcels comprise the universal set of location choice alternatives in the SACOG six-county region, it is necessary to both estimate and apply the location choice models using a sample of alternatives. The sampling of alternatives is done using two-stage importance sampling with replacement; first a TAZ is drawn according to a probability determined by its size and impedance, and then a parcel is drawn within the TAZ, with a size-based probability.

Some differences among the models come from the assumed model hierarchy in Table 1. For the usual work and school location models, auto ownership is assumed to be unknown, based on the assumption that auto ownership is mainly conditioned by work and school locations of household members, rather than the other way around. For the tour destinations, auto ownership levels are treated as given, and affect location choice. For university and grade school students who also work, the usual school location is known when usual work location is modeled; for other workers who also go to school, the work location is known when usual school location is modeled. For the tour destination models, all usual locations are known.

There are additional structural differences among these models. For the two usual location models (work and school), the home location is treated as a special location, because it occurs with greater frequency than any given non-home location, and size and impedance are not meaningful attributes. As a result, both of these models take the nested logit form, with all non-home locations nested together under the conditioning choice between home and non-home. In the estimation data, all workers have a usual work location and all students

297 have a usual school location, so the model does not have an alternative called “no usual
298 location”.

299 Because a large majority of work tours go to the usual work location, the work tour
300 destination model has this as a special alternative. Therefore, the model is nested, with all
301 locations other than the usual location nested together under the conditioning binary choice
302 between usual and non-usual. (Nearly all observed school tours go to the usual school
303 location. Therefore, there is no school tour destination choice model.)

304 Since there are no modeled usual locations for activities other than work and school, the
305 destination choice model of all remaining purposes is simply a multinomial logit model.

306 Two important variables in all of these models are the disaggregate mode choice logsum
307 and network distance. The logsum represents the expected maximum utility from the tour
308 mode choice, and captures the effect of transportation system level of service on the location
309 choice. Distance effects, independent of the level of service, are also present to varying
310 degrees depending on the type of tour being modeled. In nearly all cases, sensitivity to
311 distance declines as distance increases; in some cases this is captured through a logarithmic
312 form of distance. In other cases, where there is plenty of data to support a larger number of
313 estimated parameters, a piecewise linear form is used to more accurately capture this
314 nonlinear effect.

315 In most cases the models include an aggregate mode-destination logsum variable at the
316 destination. A positive effect is interpreted as the location’s attractiveness for making
317 sub-tours and intermediate stops on tours to this location. A mix of parking and employment,
318 at both the zone and parcel level, as well as street connectivity in the neighborhood, attract
319 workers and tours for non-work purposes. Also, parcel-based size variables and TAZ-level
320 density variables affect location choice.

322 **3.4.2 Locations of Intermediate Stops**

323
324 For intermediate stop locations, the main mode used for the tour is already known, and so are
325 the stop location immediately toward the tour destination (stop origin), and the tour origin.
326 So the choice of location involves comparing, among competing locations, (a) the impedance
327 of making a detour to get there, given the tour mode, and (b) the location’s attractiveness for
328 the given activity purpose. The model is a multinomial logit (MNL).

329 Trip characteristics used in the model include stop purpose, tour purpose, tour mode,
330 tour structure, stop placement in tour, person type, and household characteristics. The most
331 important characteristics are the tour mode and the stop purpose. The tour mode restricts the
332 modes available for the stop, and this affects the availability and impedance of stop locations.
333 The availability and attractiveness of stop locations depend heavily on the stop purpose.
334 Tour characteristics also affect willingness to travel for the stop, and the tendency to stop
335 near the stop or tour origin. These trip and tour characteristics tend to overshadow the effect
336 of personal and household characteristics in this model.

337 The main impedance variable is generalized time, as well as its quadratic and cubic
338 forms, to allow for nonlinear effects. It combines all travel cost and time components
339 according to assumptions about their relative values. Generalized time is used, instead of
340 various separately estimated time and cost coefficients, because the intermediate stop data is
341 not robust enough to support good estimates of the relative values. Generalized time is
342 measured as the (generalized) time required to travel from stop origin to stop location and on
343 to tour origin, minus the time required to travel directly from stop origin to tour origin. It is
344 further modified by discounting it according to the distance between the stop origin and the
345 tour origin. The discounting is based on the hypothesis that people are more willing to make
346 longer detours for intermediate stops on long tours than they are on short tours.

347 Additional impedance variables used in the model include travel time as a fraction of the
 348 available time window, which captures the tendency to choose nearby activity locations if
 349 there are tight time constraints on the stop, and proximity variables (inverse distance), which
 350 capture the tendency to stop near either the stop origin or the tour origin.
 351

352 **3.5 Mode Choice Models**

353 **3.5.1 Tour Main Mode**

354 The tour mode choice model determines the main mode for each tour (a small percentage of
 355 tours are multi-modal), There are eight modes, although some of them are only available for
 356 specific purposes. They are listed below along with the availability rules, in the same priority
 357 order as used to determine the main mode of a multi-mode tour:
 358

- 359 (1)
- 360 Drive to Transit: Available only in the Home-based Work model, for tours with a valid drive
 361 to transit path in both the outbound and return observed tour
 362
- 363 (2)
- 364 Walk to Transit: Available in all models except for Home-based Escort, for tours with a valid
 365 walk to transit path in both the outbound and return observed tour periods.
 366
- 367 (3)
- 368 School Bus: Available only in the Home-based School model, for all tours.
 369
- 370 (4)
- 371 Shared Ride 3+: Available in all models, for all tours.
 372
- 373 (5)
- 374 Shared Ride 2: Available in all models, for all tours.
 375
- 376 (6)
- 377 Drive Alone: Available in all models except for Home-based Escort, for tours made by
 378 persons age 16+ in car-owning households.
 379
- 380 (7)
- 381 Bike: Available in all models except for Home-based Escort, for all tours with round trip road
 382 distance of 30 miles or less.
 383
- 384 (8)
- 385 Walk: Available in all models, for all tours with round trip road distance of 10 miles or less.
 386

387 Transit has less than 1percent mode share and Bicycle has less than 2 percent mode
 388 share for all purposes except Work and School. In order to get enough transit and bicycle
 389 tours to provide reasonable estimates, the home-based non-mandatory purposes of shopping,
 390 personal business, meal and social/recreation were grouped in a single model, but using
 391 purpose-specific dummy variables to allow for different mode shares for different purposes.
 392

393 In general, it was possible to obtain significant coefficients for out-of-vehicle times, but
 394 not for travel costs or in-vehicle times. This is a typical result for RP data sets, particularly
 395 when there are few transit observations. As a result, many of the coefficients for cost and in-
 396 vehicle time were constrained at values that met the following criteria: (1) the in-vehicle time
 coefficients meet the United States Federal Transit Administration (FTA) guidelines, (2) the
 imputed values of time are reasonable and meet FTA guidelines, and (3) the values were kept
 as close as possible to what the initial estimation indicated. The resulting values of time and
 out-of-vehicle/in-vehicle time ratios are shown in Table 3. The number of transfers was not
 found to be significant in any of the models, however transfer wait time is included in the
 out-of-vehicle time coefficients. Also, the higher the percentage of time in a Drive to Transit
 path that is spent in the car rather than on transit, the lower the probability of choosing it.

397
398
399

This is a result often found in other cities as well, which serves to discourage park-and-ride choices that include long drives followed by short transit rides.

| Model | Value of time (\$/hr) | Ratio Walk to In-Vehicle | Ratio Wait to In-Vehicle |
|-------------------|-----------------------|--------------------------|--------------------------|
| Home-Based Work | \$11.20 | 2.95 | 2.50 |
| Home-Based School | \$6.00 | 2.20 | 2.20 |
| Home-Based Escort | \$7.50 | 3.00 | N/A |
| Home-Based Other | \$7.50 | 2.72 | 2.72 |
| Work-Based | \$7.50 | 2.84 | 2.84 |

400

Table 3: Tour Mode Choice Level of Service Coefficient Summary

401
402

Two land use variables came out as significant in many of the models, increasing the probability of walk, bike and transit:

403
404
405
406
407

Mixed use density: This is defined as the geometric average of retail and service employment (RS) and households (HH) within a half mile of the origin or destination parcel ($= RS * HH / (RS + HH)$). This value is highest when jobs and households are both high and balanced. High values near the tour origin tend to encourage walking and biking, while high values near the tour destination more often encourage transit use.

408
409
410
411
412

Intersection density: This is defined as the number of 4-way intersections plus one half the number of 3-way intersections minus the number of 1-way “intersections” (dead ends and cul de sacs) within a half mile of the origin or destination parcel. Higher values tend to encourage walking for School and Escort tours, where safety for children is an issue, and also to encourage walking, biking and transit for Home-Based Other tours.

413
414

A number of different nesting structures were tested. In the nesting structure that was selected there are three combined nests:

415
416
417

- (1) Drive to Transit with Walk to Transit
- (2) Shared Ride 2 with Shared Ride 3+
- (3) Bike with Walk

418
419
420
421
422
423
424

These all gave logsum coefficients less than 1.0 but not significantly different from each other, so a single estimated nesting parameter applies to all 3 nests (as well as to the 2 additional “nests” that only have one alternative each: Drive Alone, and School Bus). The estimated logsum parameters are 0.51 for Work, 0.86 for School, and 0.73 for Other. For Work-Based tours, it was not possible to obtain a stable estimate, so a constrained value of 0.75 (similar to HBOther) was used. No nesting was used for the Escort model, as it contains only 3 alternatives and is a very simple model.

425

426
427

3.5.2 Trip Mode

428
429
430
431
432
433

The trip-level mode is conditional on the predicted tour mode, but now uses a specific OD pair and a time anchor, and also the trip mode for the adjacent, previously modeled trip in the chain. The majority of tours use a single mode for all trips, so this model only explains the small percentage of trips that are made by modes other than the main mode. The most common occurrence of this is a Drive Alone trip that is made as part of a Shared Ride tour after the passenger has been picked up or dropped off. These cases are most common on

434 Escort tours, where predicting the trip(s) that is Drive Alone is mainly a function of the half
 435 tour (away from home or towards home) and the time of day.
 436

437 **3.6 Auto Availability Model**

438
 439 This model is applied at the household level, and determines the number of vehicles available
 440 to the household drivers. It is structured as a multinomial logit (MNL) with five available
 441 alternatives: 0, 1, 2, 3, and 4+. Key variables are the numbers of working adults, non-
 442 working adults, students of driving age, children below driving age and income. Statistically
 443 significant policy variables affecting car ownership include mode choice logsums measuring
 444 accessibility to the workers' and students' usual work and school locations, a mode-
 445 destination choice logsum measuring accessibility from home to non-work activities, distance
 446 from home to the nearest transit stop, parking prices in the home neighborhood, and
 447 commercial employment in the home neighborhood. Although the policy variables are
 448 significant, the model's auto ownership elasticity with respect to changes in these variables is
 449 less than 0.1 in nearly all cases and often much lower, the lone exception being very low
 450 income households.
 451

452 **3.7 Time of Day/Activity Scheduling Models**

453
 454 DaySim employs a method of modeling time of day developed by Vovsha and Bradley
 455 (2004). The time of day models explicitly model the 30 minute time periods of arrival and
 456 departure at all activity locations, and hence for all trips between those locations. It thereby
 457 also provides an approximate duration of the activity at each activity location. The model
 458 uses 48 half-hour periods in the day—3:00-3:29 AM, 3:30-3:59 AM, ..., 2:30 AM-2:59 AM.
 459 Given the way that the activity diary data was collected, no tour begins before 3:00 AM or
 460 ends after 2:59 AM. DaySim includes two types of time-of-day models:
 461

462 **3.7.1 Tour Primary Destination Arrival and Departure Time**

463
 464 For each home-based or work-based tour, the model predicts the time that the person arrives
 465 at the tour primary destination, and the time that the person leaves that destination to begin
 466 the return half-tour. The tour model includes as alternatives every possible combination of
 467 the 48 alternatives, or $48 \times 49 / 2 = 1,176$ possible alternatives. The model is applied after the
 468 tour primary destination and main mode have already been predicted. Since entire tours,
 469 including stop outcomes, are modeled one at a time, first for work and school tours and then
 470 for other tours, the periods away from home for each tour become unavailable for
 471 subsequently modeled tours.
 472

473 **3.7.2 Intermediate Stop Arrival or Departure Time**

474
 475 For each intermediate stop made on any tour, this model predicts either the time that the
 476 person arrives at the stop location (on the first half tour), or else the time that the person
 477 departs from the stop location (on the second half tour). On the second (return) half tour, we
 478 know the time that the person departs from the tour primary destination, and, because the
 479 model is applied after the stop location and trip mode have been predicted, we also know the
 480 travel time from the primary destination to the first intermediate stop. As a result, we know
 481 the arrival time at the first intermediate stop, so the model only needs to predict the departure
 482 time from among a maximum of 48 alternatives (the same 30 minute periods that are used in

483 the tour models). This procedure is repeated for each intermediate stop on the half tour. On
 484 the first (outbound) half tour, the stops are simulated in reverse order from the primary
 485 destination back to the tour origin, so we know the departure time from each stop and only
 486 need to predict the arrival time. As stops within a tour are modeled, the periods occupied by
 487 each modeled stop become unavailable for subsequently modeled stops and tours.

488 A key concept in the time of day models is the “time window”. A time window is a set
 489 of contiguous time periods that are available for scheduling tours and stops. When a tour or
 490 stop is scheduled, the portion of the window that it does not fill is left as two separate and
 491 smaller time windows. The time periods at either end of a scheduled sequence of activities
 492 on a tour are only partially filled, but the time periods in between are completely filled. It is
 493 possible to arrive at a tour or stop destination in a given time period if another tour ended in
 494 that period, and possible to leave a tour or stop destination if another tour began in that
 495 period, but it is not possible to arrive or depart in a time period that is already completely
 496 filled.

497 Another key aspect is the use of shift variables. These are dummy variables interacted
 498 with the arrival time and the duration of the alternative. If the arrival shift coefficient is
 499 negative, it means that activities tend to be made earlier (because the shift coefficient causes
 500 later arrival time alternatives to have lower utility), and if it is positive, it means that
 501 activities tend to be made later. If the duration shift coefficient is negative, it means that
 502 activities tend to be shorter (because the shift coefficient causes longer duration time
 503 alternatives to have lower utility), and if it is positive, activities tend to be longer. No
 504 departure shift coefficient is estimated because the departure shift is simply the sum of the
 505 arrival shift and the duration shift (e.g. if the arrival shift is an hour earlier and the duration
 506 shift is an hour longer, the departure shift is 0). In the models, shift variables interact
 507 extensively with other characteristics of the person, day activity pattern and tour, as well as
 508 time-dependent attributes of the network, such as travel times and measures of congestion, to
 509 effectively represent their influence on time-of-day choice.

510 The time of day models also use a variety of variables to represent scheduling pressure,
 511 conditional on what other activities have already been scheduled or remain to be scheduled
 512 for the day. The overall scheduling pressure is given by the number of tours remaining to be
 513 scheduled divided by the total empty window that would remain if an alternative is chosen.
 514 The negative effect indicates that people are less likely to choose schedule alternatives that
 515 would leave them with much to schedule and little time to schedule it in. A similar variable is
 516 the number of tours remaining divided by the maximum consecutive time window. This is
 517 also negative, meaning that people with more tours to schedule will tend to try to leave a
 518 large consecutive block of time rather than two or more smaller blocks.

519 Relative travel times across the day also influence time of day choice. The travel time
 520 for each period is based on the network travel times for the 4 periods of the day – AM peak,
 521 midday, PM peak, and off-peak. The variable is applied for both the outbound half tour (tour
 522 origin to tour destination) and the return half (tour destination to tour origin). For auto tours,
 523 the time is just the in-vehicle time, while transit time is in-vehicle time plus first wait time,
 524 transfer time, and drive access time. Walk access/egress time is not included, as that does not
 525 vary by time period. These variables are not applied for walk, bike or school bus tours.
 526 Significant travel time effects were found for Work and Other tours and for Intermediate
 527 Stops, but not for School or Work-based Tours.

528 Auto congestion may also cause time shifts within the AM peak and PM periods. For
 529 this purpose, the variable used was the extra time spent on links where the congested time is
 530 over 20 percent higher than the free flow time. This extra congested time was converted to
 531 shift variables by multiplying by the time difference between the period and the “peak of the
 532 peak”:

1. AM shift earlier: If the period is 6 AM to 8 AM, multiply by (8 AM – time)
2. AM shift later: If the period is 8 AM to 10 AM, multiply by (time – 8 AM)
3. PM shift earlier: If the period is 3 PM to 5 PM, multiply by (5 PM – time)
4. PM shift later: If the period is 5 PM to 7 PM, multiply by (time – 5 PM)

With this formulation, the more positive the coefficient and the larger the congested time, the more that the peak demand is spread away from the peak of the peak.

For Work tours, in both the AM and PM, the estimation results show a tendency to move the work activity earlier as the time in very congested conditions increases. For School tours and Work-based sub-tours, no significant congestion effects were estimated. For Other tours, times in the PM peak were found to shift both earlier and later with high congestion.

4 SACSIM System Equilibration

In the overall system design of SACSIM, Figure 1 shows a cyclical relationship between network performance and trips: DaySim and the auxiliary trip models use network performance measures to model person-trips, which are then loaded to the network, determining congestion and network performance for the next iteration. The model system is in equilibrium when the network performance used as input to DaySim and the other trip models matches the network performance resulting from assignment of the resulting trips. Network performance for this purpose is times, distances, and costs measured zone-to-zone along the paths of least generalized cost.

Trip-based model systems with this same requirement have existed for at least thirty years (Evans, 1976), and the theory of system equilibrium for them is well developed now. Almost all convergent trip-based models, at some stage in an iteration process, use the method of convex combinations. This is to update the current best solution of flows (zone-to-zone matrices and/or link volumes) with a weighted average of the previous best solution of those flows and an alternative set of flows calculated by the new iteration.

With the unit of analysis in DaySim being households instead of origin-destination pairs, we have options that are not normally available to trip-based models. DaySim need not simulate the entire synthetic population in an iteration; it is able to run a selected sample of the population. Since its runtimes are long but proportional to the number of households modeled, early system-iterations can be sped up by simulating small samples.

The SACSIM equilibration procedure employs equilibrium assignment iteration loops (a-iterations) nested within iterations between the demand and assignment models (da-iterations). This is similar to the nested iteration in many trip-based model systems. Assignment is run for four time periods, and each one employs multi-class equilibrium assignment, with classes composed of SOV, HOVs not using median HOV lanes, and HOVs using them. In the i -th da-iteration, DaySim is run on a subset of the synthetic population, consisting of the fraction $1/s_i$ (i.e. $100/s_i$ percent) of the households, starting with the m_i -th household and proceeding uniformly every s_i households. The user determines s_i and m_i . DaySim scales up the synthesized trips by the factor s_i before they are combined with the estimated external, airport and commercial trips in mode-specific OD matrices for the four assignment time periods. During the n -th a-iteration within the i -th da-iteration, link volumes are estimated for the iteration i OD matrices, and combined in a convex combination with link volumes from the prior da-iteration, using a user-specified combination factor (or step-size) λ_i . This is the pre-loading method intended to prevent link volume oscillation between da-iterations. The resulting estimated volumes are then combined with link volumes from the prior a-iteration using the TP+-determined step size α . This is intended to prevent link volume oscillation between a-iterations.

583 As implemented, the equilibration procedure runs for a user-determined number (I) of
 584 da-iterations. Within each iteration, the user controls the synthetic population subset used by
 585 DaySim (via s_i and m_i), the weight (λ_i) given during assignment to the link volumes
 586 associated with this iteration's simulated trips, and the assignment closure criteria (N_i and g_i).
 587 Bowman, Bradley and Gibb (2006) report the results of testing various combinations of these
 588 parameters.

589 Eventually, certain applications of the activity model may need the equilibrium process
 590 to achieve higher precision in zone-to-zone times than the prototypical applications provide.
 591 Since the degree of precision is problem-specific (depends on the population and on
 592 congestion levels), empirical study should be pursued as needed on where to best find
 593 improvement, in either: (a) more system iterations with smaller step sizes and/or smaller first
 594 sample, (b) more simulation passes per household, (c) a smaller tolerance of the assignment's
 595 relative gap closure criterion, especially in later system iterations, or (d) some combination of
 596 these. A separate requirement anticipated for some applications of SACSIM is to reduce the
 597 randomness of trip forecasts beyond what is inevitable from the Monte Carlo process at full
 598 sampling. These applications require supersampling, which is running two or more
 599 simulations of the whole population after equilibrium is adequately achieved, and averaging
 600 their results.
 601

602 **5 SACSIM Calibration and Validation**

603
 604 SACSIM calibration and validation work has proceeded in three steps: preliminary
 605 validation, base year calibration, and prediction validation. Preliminary validation involved
 606 comparing model estimation and software application results to the household survey sample.
 607 It occurred primarily during DaySim model estimation and software development. After
 608 each model was estimated, it was applied to the survey data. Aggregate results for various
 609 subpopulations were checked, as were model sensitivities, to detect deficiencies in the model
 610 specifications, so they could be corrected. After each model was implemented in the
 611 application software, it was again compared to the survey sample to find software bugs.

612 A base year validation run consisted of running a base year 2000 scenario of the entire
 613 model system to an equilibrated state, and comparing aggregate results to the best available
 614 external information about the actual base year characteristics on a typical weekday. This
 615 information comes from census data, transit on-board surveys, and screenline and other
 616 counts. Calibration then involved iteratively adjusting parameters and repeating validation
 617 runs until the base year prediction adequately matches the external information. Although all
 618 model calibration adjustments have a simultaneous impact on the model predictions, it is
 619 natural to calibrate sequentially from the top to the bottom of the DaySim model hierarchy,
 620 because adjustments to upper level models will tend to impact lower level model predictions
 621 more than vice versa. Bowman and Bradley (2006) provide some further details on the initial
 622 calibration tests.

623 Overall model validation was performed by comparing key model outputs to observed
 624 travel patterns for Years 2000 and 2005. Long term models (usual place of work and auto
 625 ownership) were validated against the 2000 Census. Short term models (day pattern, tour and
 626 trip frequency, tour and trip distribution and timing) were validated against the 2000
 627 household travel survey. Aggregate assignment outputs for both transit and highway were
 628 validated against traffic counts (daily volumes, and direction volumes by four time periods)
 629 and transit volumes (daily passenger volumes by line, and daily station boardings for rail
 630 stations). The *SACSIM07 Model Reference Report* (SACOG 2008a) provides details of the
 631 model calibration and validation results,

6 Sensitivity Testing and Evaluation

Two sorts of sensitivity evaluations were performed on SACSIM: cross sectional evaluations of travel sensitivity to land use variables, and “experimental” travel sensitivity to key exogenous variables. Cross-sectional evaluations of land use sensitivity focused on correlation of travel to so-called “4D’s” variables such as density, mix of use, street pattern, and transit proximity. Comparisons of SACSIM sensitivity to these land use variables to observed sensitivity in the 2000 household travel survey were made for each variable. Because SACSIM input and output files are parcel-point geography, characteristics of land use at place of residence or place of work can be described in much greater detail, and matched to similar characteristics observed in the travel survey in a way that is not possible if the model aggregates land uses to traffic analysis zones. Figures 3 and 4 show how land use density (jobs plus dwelling units) within a quarter mile buffer around the residence parcel is related to daily VMT per household and non-auto mode share. The difference in behavior found in the survey households related to this density variable is quite dramatic, and the SACSIM predictions match the observed trends quite well. This ability to capture detailed neighborhood density effects is a result of the fact that the models use parcel-level detail, and that they use a variety of urban design variables.

Travel sensitivities to transit fares, auto fuel cost, highway capacity, and household income were tested experimentally, by synthetically increasing or decreasing the test variable, and correlating changes in model outputs to the test variables. A summary of sensitivity test results is given in Table 4. For these tests, reasonability of the travel model sensitivity was judged by comparison to sensitivities observed in other research. For example, the transit fare elasticity is roughly $-.23$, which is in the typical range. The cross-elasticities for the other modes and for total trips are quite low, due to the fact that the transit mode share is very low to begin with, so mode shifts from transit have little relative effect on the other modes.

The auto fuel cost elasticity on VMT is roughly $-.13$. This is somewhat lower than the typical long term fuel price elasticity estimated from time series data ($-.2$ to $-.3$), and there is clearly a question as to how accurately cross-sectional data from a period of stable fuel prices can capture behavioral responses to fuel price. Also, the tests below were done for the 2005 situation, when there are few non-auto alternatives in several parts of the region. In additional scenarios run for 2035, with more compact land uses and increased transit service, the fuel price elasticity for the forecasts appears somewhat higher, around $-.18$.

The estimated elasticity of VMT with regard to highway capacity ($+.144$) also appears somewhat low, as time series analysis has revealed values in the range of $+.3$ to $+.6$. Note, however, that this sensitivity test was done not by adding new highway links, but simply by increasing the capacity on all existing road network links, regardless of the level of congestion. In real situations, roads tend to added and widened only where congestion levels are highest, so it is reasonable that the effect on demand would be higher. Further sensitivity tests could be done to more closely mimic real-world highway capacity improvements.

675

7.1 Application Issues

713

714

715

716

717

718

719

The most time-consuming application issue has been the development of forecast year parcel/point datasets required by SACSIM. As this has been the first model system of its kind to work at the parcel level, SACOG and the model developers needed to devise procedures for developing forecast year spatial data, with no examples from models developed elsewhere. We trust that our experiences from this project will prove useful to others who will be developing parcel-based travel demand models in the future.

720 Development of the model was based on parcel/point data from Year 2000 surveys and
721 inventories of population, employment and land use. Application of the model was based on
722 synthesized datasets for the model base year (2005) and for all forecast years for the MTP.
723 The *SACSIM07 Model Reference Report* (SACOG 2008a) provides a detailed discussion on
724 the preparation of the model input data.

725 The primary parcel/point data source was SACOG's parcel-based land use database,
726 called Place3s. Place3s is a GIS-based land use scenario generator (Allen, et al. 1996).
727 Scenarios are built at parcel level, with land uses characterized by "place type", which
728 includes assumptions about the type, density, and mix of uses. SACOG uses a palette of
729 about 50 place types. Total development levels are controlled by aggregate county-level
730 econometric forecasts adopted by the SACOG Board for use in the development of the MTP.
731 Place3s was used to estimate dwelling units and employment (9 sectors) at parcel level.

732 Even with the basic demographic variables forecasted at parcel level, other datasets that
733 are very important for predicting travel behavior do not come naturally from Place3s, and
734 were prepared separately. These variables include: small-area demographics needed to
735 control the development of synthetic populations; K12 schools, colleges and universities;
736 some sectors of employment (e.g. medical employment not associated with hospitals and
737 large medical centers); paid off-street parking facilities; transit stops; and street-pattern
738 variables.

739 Demographics to control the development of synthetic populations were built up from
740 the Place3s parcel-level estimates for dwelling units. The control variables for the population
741 synthesis are household size (1,2,3,and 4+ persons); workers per household (0,1,2, and 3+
742 workers); income level (5); and age of head-of-household (over/under 55 years).
743 Demographic profiles based on control variables for three dwelling unit structure types
744 (single family, multi-family 2-4 units, and multi-family 5+ units) were drawn from Year
745 2000 Census tabulations for regional analysis districts within the region. The profiles are
746 applied to the Place3s estimates of dwellings by type at traffic analysis zone level. The
747 resulting files are used directly by SACOG's 4-step travel model (SACMET), and are used as
748 control files for the SACSIM population synthesis.

749 School locations and types are built up at point-level from a Year 2005 inventory of
750 schools to future years by adding future schools. For K12 schools, future school needs are
751 calculated at TAZ-level by tallying growth in school-age children in the synthetic
752 populations. For example, the Year 2035 land use forecasts require about 300 new K12
753 schools. Where possible, future school sites are identified in local agency general plans and
754 school district plans. In practice, only a minority of future K12 sites are explicitly identified
755 in planning documents, and the majority of future K12 sites are manually identified based on
756 the location of residential growth and judgment. Future colleges and universities are based
757 on known plans for these facilities.

758 Place3s estimates medical employment associated with hospitals and large medical
759 centers. All other medical employment associated with smaller clinics, private offices, and
760 other medical-related uses are included within estimates of office and service employment
761 sectors. Other medical employment is split out from these more aggregate categories based
762 on proximity of parcel to the hospitals and large medical centers. For parcels very near
763 hospitals/medical centers, a higher percentage of the total office/service employment is
764 medical; as distance increases, the percentage decreases. Rates for this post-processing were
765 based on Year 2005 employment inventories.

766 Paid off-street parking facilities are built up at point-level from a Year 2005 inventory in
767 a manner similar to the build-up of K12 schools. The growth in paid off-street parking
768 spaces is calculated at TAZ level, based on the growth in employment by density range. In
769 general, paid off-street parking is directly related to density of development: as the density of

770 development on a parcel increases, the likelihood of paid off street parking, and prices
 771 charged, increases. The “yields” of paid off-street parking are calculated at TAZ-level based
 772 on the amount of growth in several density ranges, with facility locations identified based on
 773 judgment within each TAZ. The yield rates were computed from a Year 2005 inventory of
 774 parking facilities, and Year 2005 Place3s development density estimates. Paid parking is
 775 also related to special uses, like colleges/universities and hospitals, and facilities are added at
 776 future locations of these uses.

777 Proximity to transit is measured as orthogonal distance from parcel to the nearest transit
 778 station or stop in SACSIM. Transit stops are also built up at point level from a Year 2005
 779 inventory of transit stops. New future transit stop points are based on a comparison of
 780 forecast year and Year 2005 transit networks from the travel demand model. Where new
 781 transit lines are added, new stops are added to the inventory. In areas with little or no change
 782 in transit service, the Year 2005 stop inventory is used. For rail and express bus facilities,
 783 stations and stops as coded in the travel demand model are used directly. For fixed route bus
 784 services, the travel demand model stops under-predict actual stops. This is because zone-
 785 based travel models do not include sufficient detail to capture the stop-spacing for local bus
 786 routes, especially in urban areas. In these areas, stops points are synthesized along the bus
 787 routes and added to the Year 2005 inventory points.

788 Street pattern variables are used in several location and mode choice models in
 789 SACSIM, and are strongly related to non-motorized mode choice. The key street pattern
 790 variables are the buffered densities or numbers of intersections of three types: 1-leg
 791 intersections (e.g. cul-de-sacs); 3-leg intersections (e.g. a “T”); and 4+-leg intersections (e.g.
 792 a four-way intersection). Higher levels of 1-leg intersections are associated with lower
 793 likelihood of trip linking and non-motorized modes of travel; higher levels of 3- and 4+-
 794 leg intersections are associated with higher likelihood of trip linking and non-motorized travel
 795 modes. While future densities and mixes of use in growth areas are captured in the Place3s
 796 land use scenarios, future street pattern is not. Street patterns profiles for growth areas are
 797 “borrowed” from Year 2005 observed street patterns by place type and density level.

798 Each one of these data issues required significant time and effort to address. However,
 799 with the exception of transit stops, the data are prepared only once for each land use data run,
 800 and the process is becoming more routinized and efficient. Virtually all of these issues need
 801 to be addressed for zone-based models, but the aggregate nature of the zones allows for the
 802 data to be developed with less rigor and hand-wringing. The discipline of developing the
 803 datasets at parcel/point level simply requires that all the assumptions be laid out explicitly.
 804

805 **8 Peer Review Assessment and Recommendations**

806 The SACSIM model system was the subject of a two-day peer review session, sponsored by
 807 the FHWA Travel Model Improvement Program (TMIP) in November 2008 (SACOG
 808 2008c). All members of the peer review panel had experience with implementing activity-
 809 based models—four from the MPO perspective, and one from the model developer
 810 perspective.
 811

812 In general, the review panelists were very positive about the SACSIM model system.
 813 The aspects of the activity-based model component (DaySim) that the review panel
 814 commended most highly were:

- 815 • The parcel-based approach
- 816 • The tour-based approach (day-tour- trip hierarchy, time of day scheduling)
- 817 • Treatment of university students throughout the model (UC-Davis and Sacramento
 818 State Univ.), including a separate population synthesis for on-campus housing.
- 819 • The rigorous sensitivity testing performed

A variety of possible enhancements to the model system were also discussed. The specific improvements that the panel deemed highest priority were:

- Related to road pricing:
 - Update the value-of-time coefficients, and improve the treatment of price (for example, a toll versus non-toll nest as part of mode choice)
 - Move to distributed values-of-time (a separate VOT for each person/tour, drawn from distribution)
- Related to destination choice:
 - Change the specification of destination choice models to rely less on distance, and more on mode choice logsums and other mode level of service measures
- Related to mode choice:
 - Move toward adding additional pedestrian and bicycle supply variables to the model (examples are sidewalk and bicycle lane coverage as a percentage of street distance within walking/biking distance around each parcel)

The last improvement mentioned above illustrates the type of additional detail that a parcel-level model can accommodate in order to allow analysis of urban design and non-motorized travel. It is likely that such urban infrastructure data will be readily available in digital form for most MPO's in the near future.

9 Conclusions

This article provides a detailed overview of the first parcel-based, activity-based travel demand model system to be used in urban forecasting, to the authors' knowledge. The model system was used to provide the forecasts for the latest Regional Transportation Plan (RTP) for the Sacramento region, and a Federal peer review of the model system was carried out. We can conclude that it is possible to create and apply a regional demand model system using parcel-level geography and half-hour time of day periods. Experiences thus far have pointed to major benefits of using detailed land use variables and urban design variables, but also to new challenges in providing parcel-level land use inputs for future years. Further research is under way to integrate parcel-level travel demand microsimulation models with land use models such as PECAS (in the Sacramento region) and UrbanSim (in the Seattle region). In addition, Federal research projects are now underway to integrate the SACSIM model with dynamic traffic simulation models such as TRANSIMS and DYNUS-T, which can fully take advantage of the finer spatial and temporal detail in the travel demand forecasts, and can in turn provide DaySim with more accurate predictions of highway travel times and congestion.
